A Pooled Analysis of the Effect of Condoms in Preventing HSV-2 Acquisition

Emily T. Martin, MPH; Elizabeth Krantz, MS; Sami L. Gottlieb, MD, MSPH; Amalia S. Magaret, PhD; Andria Langenberg, MD; Lawrence Stanberry, MD, PhD; Mary Kamb, MD, MPH; Anna Wald, MD, MPH

Background: The degree of effectiveness of condom use in preventing the transmission of herpes simplex virus 2 (HSV-2) is uncertain. To address this issue, we performed a large pooled analysis.

Methods: We identified prospective studies with individual-level condom use data and laboratory-defined HSV-2 acquisition. Six studies were identified through a review of publications through 2007: 3 candidate HSV-2 vaccine studies, an HSV-2 drug study, an observational sexually transmitted infection (STI) incidence study, and a behavioral STI intervention study. Study investigators provided us individual-level data to perform a pooled analysis. Effect of condom use was modeled using a continuous percentage of sex acts during which a condom was used and, alternatively, using absolute numbers of unprotected sex acts.

Results: A total of 5384 HSV-2–negative people at baseline contributed 2,040,894 follow-up days; 415 persons acquired laboratory-documented HSV-2 during follow-up. Consistent condom users (used 100% of the time) had a 30% lower risk of HSV-2 acquisition compared with those who never used condoms (hazard ratio [HR], 0.70; 95% confidence interval [CI], 0.40-0.94) (P=.01). Risk for HSV-2 acquisition increased steadily and significantly with each unprotected sex act (HR, 1.16; 95% CI, 1.08-1.25) (P<.001). Condom effectiveness did not vary by gender.

Conclusions: To our knowledge, this is the largest analysis using prospective data to assess the effect of condom use in preventing HSV-2 acquisition. Although the magnitude of protection was not as large as has been observed with other STIs, we found that condoms offer moderate protection against HSV-2 acquisition in men and women.

Arch Intern Med. 2009;169(13):1233-1240

STUDIES THAT PROSPECTIVELY measure sexual activity, condom use, and sexually transmitted infection (STI) incidence are necessary to assess preventive effect of condom use on STI acquisition. In the absence of randomized controlled trials, the best evidence available on condom use and STI acquisition comes from prospective observational studies, or intervention trials conducted for other purposes in which the STI of interest was an end point. Compelling evidence from such studies indicates that consistent condom use reduces transmission of human immunodeficiency virus (HIV). Additionally, increasingly strong data support condom effectiveness in preventing STIs that target urethral or cervical epithelia, such as chlamydia and gonorrhea. However, the effectiveness of condoms in preventing the transmission of herpes simplex virus 2 (HSV-2) is less certain. A 2001 panel convened by the National Institute of Allergy and Infectious Diseases concluded that the available evidence on condom effectiveness was insufficient to establish that condoms were protective against HSV-2 acquisition because the research was derived from studies that used prevalent HSV-2 infection as the outcome and thus were unable to determine the temporal relationship between condom use and HSV-2 acquisition. Since that time, 3 studies have been published that show moderate efficacy (approximately 50%) for condom use. However, in these studies, measures of condom use and definitions of condom effectiveness differed. More precise measurement of condom efficacy, with attention to subgroups in which condom effectiveness may differ, is desirable.

In this study, we sought to increase the precision of the estimates of condom use on HSV-2 acquisition by pooling data from...
all published studies that prospectively assessed condom use and HSV-2 incidence. We performed an individual-level pooled analysis that combined prospective data from such studies to assess the relationship between condom use and time to HSV-2 acquisition. In addition, we performed additional analyses to assess the relationship between the absolute number of unprotected sex acts per week and HSV-2 acquisition.

**METHODS**

**DATA COLLECTION**

We sought to identify all relevant studies for this analysis by conducting literature searches as well as discussions with other researchers in the field. First, we conducted a PubMed search of studies published through October 2004 using the terms “genital herpes AND condom” and “herpes AND condom.” The initial search resulted in 147 articles that were reviewed for inclusion according to 3 predetermined eligibility criteria: (1) use of prospective cohort study design in which participants were tested with type-specific HSV-2 antibody tests at baseline and follow-up; (2) assessment of both condom use and frequency of sexual activity throughout the study; and (3) laboratory documentation (either culture analysis, polymerase chain reaction assay, or type-specific serologic analysis) of HSV-2 acquisition. From this review, we identified 21 studies as potentially eligible, 17 of which did not meet the inclusion criteria.11-27 Six studies documented in 5 reports met our predetermined criteria (Table 1),28-32 including 4 identified through the literature review process26-30 and 2 identified through asking researchers in the field about their knowledge of studies meeting the eligibility criteria.31,32 We included 2 HSV-2 vaccine studies, 1 observational STI incidence study,28 and 1 HIV behavioral intervention study (Table 1).29 All studies incorporated safer sex counseling as part of their routine follow-up.

Next, we asked the investigators to provide individual-level data from the eligible studies. We were provided data for all participants in 4 studies (3 reports)28-30 and for the placebo arm part-

porting having multiple partners despite their participation in a couples study because some persons re-
cluded in the models as a categorical variable (0-1, 2, 3-5, 6-10, values).

duced across each data set. The frequency of genital or anal sex acts and the proportion of condom use for sex acts were available in each study. For studies that reported categories of condom use (such as “never,” “sometimes,” or “always”), the corresponding ranges of percentage condom use for each category were obtained from the study questionnaire. The numeric value at the midpoint of each response category’s range was used in analyses that included condom use as a continuous variable. We included only particip-

cated by using indicator variables for “African American” and “other,” with “white” used as the reference group. This variable was included because of the higher incidence of HSV-2 in African Americans. When values for potential risk factors were missing, data from previous visits up to 6 months before the time of the missing data were car-

n the study were excluded because they reported no sexual activity or underwent no laboratory tests or had no interview on condom use during the follow-up period: 10 from Corey et al (vaccine partners), 118 from Corey et al (vaccine STI clinic), 40 from Corey et al (valacyclovir), 38 from Kamb et al (Project RESPECT), 260 from Noell et al (adolescents), 9 from Stan-

e of unprotected sex acts was determined by computing study-specific and overall means or medians of these values. A univariate Cox regression model stratified by study was generated for each potential risk factor and tested using a like-

date of HSV-2 acquisition were set at the mid-

tical variable with categories for values 0, 1, 2, 3, and 4 or more. The effect of an increasing number of unprotected sex acts on risk of HSV-2 acquisition was estimated using a Cox regression model stratified by study. An adjusted model for the effect of unprotected sex acts included interaction terms for frequency of unprotected sex acts by study and by gender.

All reported P values are 2 sided. All statistical analyses were performed with STATA 8.0 software (StataCorp, College Station, Texas).

The association between condom use and the risk of HSV-2 acquisition was initially evaluated with a Cox regression model stratified by study and controlling for categorical number of sex acts by week. Condom use was included in the model as a contin-

uous variable (percentage of sex acts during which a condom was used). Coefficients were multiplied by 25 to ascertain the aggregate effect of condoms for every 25% increase in use. We exam-
in the models. Coefficients were multiplied by 25 to ascertain the aggregate effect of condoms for every 23% increase in use. We exam-
ined whether the effect of condom use differed by gender using an interaction term for condom use by gender. Adjusted models for the effect of condom use on the risk of HSV-2 acquisition were generated with the Hosmer and Lemeshow stepwise method. An adjusted model was generated for the effect of percentage condom use stratified on study and adjusted for number of sex acts per week and other significant co-

as were accessible across studies over the preceding time period. Race data were obtained from the original studies and categorized by using indicator variables for “African American” and “other,” with “white” used as the refer-

ent group. This variable was included because of the higher incidence of HSV-2 in African Americans. When values for potential risk factors were missing, data from previous visits up to 6 months before the time of the missing data were carried forward. Date of HSV-2 acquisition were set at the midpoint between the date of the most recent negative test result and the date of the first positive test result. Annualized inci-
dence of HSV-2 acquisition was calculated by study and gender. Continuous measures taken repeatedly on individuals were summarized by first averaging over all time points and then by computing study-specific and overall means or medians of these values. A univariate Cox regression model stratified by study was generated for each potential risk factor and tested using a like-

lihood ratio test at a significance level of .05. Stratified Cox mod-
els were used throughout the analysis to allow for differing baseline hazards between studies, possibly due to any effects of study-specific interventions, that might not satisfy the proportional hazards assumption. The proportional hazards as-
sumption was examined using plots of scaled Schoenfeld res-
iduals for univariate and multivariate models, and no violations were found. Graphical analysis was also used to assess param-

erization of continuous variables and to select cut points or categories. Number of genital or anal sex acts per week was in-
cluded in the models as a categorical variable (0-1, 2, 3-5, 6-10, >10). Age was grouped into tertiles (≤23, 24-31, >31 years) and included as a grouped linear variable. Gender, STI history (ever or never), baseline HSV-1 status, sexual orientation during the study (heterosexual or other), and monogamy (only 1 sex partner) during the study were included as binary vari-

ables. The effect of having only 1 partner vs multiple partners in a measurement period on time until HSV-2 acquisition was hypothesized to differ based on whether the subject participated in a study that recruited monogamous couples. There-

fore, an interaction was tested between number of partners and participation in a couples study because some persons re-

ported having multiple partners despite their participation in a couples study.

The 6 studies yielded a total of 5384 subjects whose base-

line HSV-2 test results were negative and who were included in this pooled analysis. Four-hundred seventy-five subjects were excluded because they reported no sexual activity or underwent no laboratory tests or had no interview on condom use during the follow-up period: 10 from Corey et al (vaccine partners), 118 from Corey et al (vaccine STI clinic), 40 from Corey et al (valacyclovir), 38 from Kamb et al (Project RESPECT), 260 from Noell et al (adolescents), 9 from Stan-
berry et al (vaccine). Overall, subjects had a mean age of 29 years; 66.2% were male; 60.4% were white; 94.1% were heterosexual; and most reported no prior STIs (Table 2). Sixty percent of the subjects were HSV-1 se-

ropositive at study entry. The 5384 subjects contributed 2,040,894 follow-up days, with a median follow-up of 374 days (range, 4-987 days).

Overall, 415 persons acquired laboratory-documented HSV-2 during follow-up. The overall incidence was 7.4 per 100 person years (95% confidence interval [CI], 6.7-8.2), but varied among studies (Table 3). Incidence was consistently higher for women than for men, though the differences between genders varied greatly (Table 3). The study-specific median frequency of sex acts averaged 1.4 per week (range, 0.6-1.9). The median number of partners reported during the study was 1 (interquartile range, 1-1.74) in the pooled data set and matched the study-specific median values except for the adoles-
cent STI incidence study50 (median, 2) and the vaccine STI clinic study50 (median, 1.4). The median percentage condom use during follow-up was lower in the studies.
that recruited discordant couples (7%, 14%, and 18% in the Corey et al \textsuperscript{29} vaccine partners, Stanberry et al \textsuperscript{31} vaccine, and Corey et al \textsuperscript{32} valacyclovir studies, respectively) compared with other studies (from 46% to 53%). In the pooled data, the median percentage of condom use was 39%, and the subject averages over study follow-up had a U-shaped distribution (\textbf{Figure 1}).\textsuperscript{44}

Variables univariately associated with HSV-2 acquisition included female gender, younger age, nonwhite race, and history of STIs (\textbf{Table 4}).

The association between a 25% increase in condom use and HSV-2 acquisition, adjusted for number of sex acts and stratified by study, indicated a weak protective effect that was not statistically significant (hazard ratio [HR], 0.95 [95% CI, 0.88-1.00]) (\textit{P} = .09). This effect did not significantly differ by gender (\textit{P} = .22 for interaction).

In a multivariate model (\textbf{Table 5}), a 25% increase in condom use significantly decreased the risk of HSV-2 acquisition (HR, 0.93 [95% CI, 0.85-0.99]) (\textit{P} = .01). Similarly, the aggregate hazard ratio for 100% condom use compared with 0% use was 0.70 (95% CI, 0.40-0.94) (\textit{P} = .01). No evidence of heterogeneity was found by study (\textit{P} = .24) or gender (\textit{P} = .22) in the adjusted model. In sepa-

Abbreviations: HSV, herpes simplex virus; STI, sexually transmitted infection.
\textsuperscript{a}Data are reported as incidences (95% confidence intervals).
rate analyses for each study, increasing condom use was found to decrease the adjusted risk of HSV-2 acquisition; however, these estimates were only statistically significant for 1 study (Figure 2). Baseline HSV-1 status, STI history, sexual orientation during the study, and monogamy during the study did not significantly predict HSV-2 acquisition during model selection and were not included in the final multivariate model.

In a univariate model stratified by study, the risk of HSV-2 acquisition increased significantly with increasing unprotected sex acts per week (0, 1, 2, 3, and ≥4) (HR, 1.10 [95% CI, 1.02-1.19]) (P = .01). After adjustment for age, race, and gender, the estimate showed an increased risk of HSV-2 acquisition with increasing numbers of unprotected sex acts per week (HR, 1.16 [95% CI, 1.08-1.25]) (P < .001) (Table 6). We found no evidence for significant variation of this effect by gender (P = .41). Overall estimates of the impact of the number of unprotected sex acts were also relatively consistent between study subgroups, except smaller effect was observed in the Project RESPECT28 and Stanberry et al31 vaccine subgroups (Figure 2). However, an interaction between study and frequency of unprotected sex acts was not significant (P = .41).

In our pooled analysis of data from all studies to date that have prospectively assessed condom use and HSV-2 incidence, we found that condom use moderately, albeit significantly, protected against HSV-2 acquisition. Persons who always used condoms had a 30% decreased risk of acquiring HSV-2 compared with persons who reported no condom use. Risk of HSV-2 acquisition decreased by 7% for every additional 25% of the time that condoms were used during anal or vaginal sex. Risk of HSV-2 acquisition also rose steadily and significantly with increasing frequency of unprotected sex acts, and our findings were consistent throughout multiple analysis strategies. Our method of pooled analysis circumvented the obstacles and expense of recruiting and following a large cohort of individuals, and the use of individual-level data in the pooled analysis allowed for uniform coding of the relevant variables and assessment of relationships that might not have been explored as part of the original results.45 Since we did not find strong evidence of heterogeneity between studies for the effectiveness of condoms, we believe that this was a valid approach.

In some cases our pooled estimates of condom effects on HSV-2 acquisition varied from earlier published reports on those studies. For example, previously published analyses of the Project RESPECT28 study data found that subjects who used condoms less than 50% of the time with occasional partners had twice the risk of acquiring HSV-2 as those with 100% condom use or no occasional partners (HR, 2.0 [95% CI, 1.2-3.3]).8 We found a lower estimate in this analysis that is likely due to the inclusion of condom use between self-reported monogamous partners; level of condom use with main partners was not associated with reduced HSV-2 acquisition in the previous analysis. Also, in an analysis of the participants study,9 Wald et al10 reported an adjusted HR of 0.085 for women (95% CI, 0.01-0.67) using condoms more than 25% of the time, but this protection was not observed in...
men. We did not find any significant differences in condom effectiveness between men and women, despite a higher incidence of HSV-2 acquisition in women (Table 3). The lack of effect reported in the earlier publication may have been related to few cases of HSV-2 acquisition in men; the large sample size in our pooled analysis allowed a more robust estimate.

The limitations of our study include the availability of only those covariates for the adjusted analyses that were collected in a consistent way across every study. For example, we were unable to adjust for some known risk factors for HSV-2 acquisition, such as the number of new sexual partners and the HSV status of each partner, which may have led to uncontrolled confounding. Warner et al. have described unmeasured confounding in a similar cohort analysis of condom effectiveness as differences between consistent and inconsistent condom users related to unmeasured factors that led to an underestimate of the magnitude of the protective effect of condoms on STI acquisition. Condom use may have been inaccurately reported owing to social desirability bias or incorrect usage, or it may have been affected by recent HSV-2 acquisition. Condom use and HSV-2 acquisition were ascertained after various follow-up intervals, and it is possible that a primary HSV-2 episode in some cases could lead to increased condom use within the same measurement interval. These misclassifications attenuate the observed estimate toward the null and are present in other studies of condom effectiveness. Additionally, we identified studies to include in this analysis through a literature search, which may have led to publication bias. We believe, but cannot be certain, that our solicitations among other investigators identified most relevant studies.

This analysis adds to the growing number of condom analyses that use an absolute number of unprotected sex acts for exposure as opposed to the more traditional measure of percentage condom use. Analyses of these 2 outcomes gave roughly the same conclusion. The unprotected sex act models may be more appropriate as they do not require the impact of percentage condom use to be consistent across varying numbers of sex acts, emphasizing that one’s risk of acquiring HSV-2 is specific to each unprotected sex act.

The 30% reduction in HSV-2 acquisition observed in this pooled analysis was less than the reported 87% reduction associated with condom use on HIV acquisition. This difference likely reflects different transmission mechanisms. While HIV is transmitted via contact with bodily fluids, HSV-2 is primarily transmitted through direct skin-to-skin or skin-to-mucosa contact. Therefore, some HSV-2 transmission can occur despite condom use when viral shedding is present in areas not covered by the condom. Nonetheless, based on findings of this large analysis using all available prospective data, condom use should continue to be recommended to both men and women for reducing risk of HSV-2 acquisition. Although the magnitude of the protective effect was not as large as has been observed with other STIs, a 30% reduction in HSV-2 incidence can have a substantial benefit for individuals as well as a public health impact at the population level.

Accepted for Publication: January 17, 2009.

Author Affiliations: Departments of Epidemiology (Ms Martin and Dr Wald), Laboratory Medicine (Ms Krantz and Drs Magaret and Wald), and Medicine (Dr Wald), University of Washington, Seattle; Seattle Children’s Hospital, Seattle (Ms Martin); Division of Sexually Transmitted Disease Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia (Drs Gottlieb and Kamb); Vaccine and Infectious Diseases Institute, Fred Hutchinson Cancer Research Center, Seattle (Drs Magaret and...
Wald); Chiron Corporation, Emeryville, California (Dr Langenberg); and Department of Pediatrics, College of Physicians and Surgeons, Columbia University, New York, New York (Dr Stanberry). Ms Krantz is now with the Department of Ophthalmology and Visual Sciences, University of Wisconsin, Madison; Dr Langenberg is now an employee of Medivation Inc.

Correspondence: Emily T. Martin, MPH, Children’s Hospital Research Institute, 1900 Ninth Ave, C9S-9C, Seattle, WA 98101 (Ejtm@u.washington.edu).

Author Contributions: Dr Wald had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study concept and design: Martin, Kamb, and Wald. Acquisition of data: Martin, Krantz, Gottlieb, Langenberg, Stanberry, Kamb, and Wald. Analysis and interpretation of data: Martin, Krantz, Magaret, and Wald. Drafting of the manuscript: Martin and Wald. Critical revision of the manuscript for important intellectual content: Martin, Kamb, Gottlieb, Magaret, Langenberg, Stanberry, Kamb, and Wald. Statistical analysis: Martin, Krantz, Magaret, and Wald. Obtained funding: Stanberry and Wald. Administrative, technical, and material support: Martin, Kamb, and Wald. Study supervision: Wald.

Financial Disclosure: Dr Langenberg is an employee of Medivation Inc. Dr Stanberry has received grant support from the National Institutes of Health and the Bill and Melinda Gates Foundation; he has been a consultant for GlaxoSmithKline, Starpharma, Novartis, and Nanobio. Dr Wald has received grant support from the National Institutes of Health, GlaxoSmithKline, Aventis, and the Bill and Melinda Gates Foundation; he has been a consultant for Novartis, Immune Design, Medigene, and Alcuris and a speaker for Merck Vaccines.

Funding/Support: Funding for this project was provided by grants P01 AI-030731 and K24 AI-107113 from the National Institutes of Health, National Institute of Allergy and Infectious Diseases (Dr Wald).

Additional Contributions: Lawrence Corey, MD, John Noell, MD, and the investigators of all the original studies included in this analysis generously shared data with us.

Correction

Incorrect x-Axis Distribution. All data in Figure 2B of “A Pooled Analysis of the Effect of Condoms in Preventing HSV-2 Acquisition” published in the July 13, 2009, issue of the Archives of Internal Medicine (2009;169[13]:1233-1240) were incorrectly distributed across the x-axis. The corrected Figure 2B with the original figure legend appears here.

Figure 2. Study-specific hazard ratios. The effects of a 25% increase in condom use (A) and increasing number of unprotected sex acts (B) on herpes simplex virus 2 (HSV-2) acquisition. The sizes of the dark squares are proportional to the inverse variance of the estimate and centered on the hazard ratio. Horizontal lines indicate the 95% confidence intervals for effect on time until HSV-2 acquisition. Diamonds are centered on the pooled hazard ratio estimate (dashed vertical line), and width indicates the 95% confidence interval.
