The difficulty that nonnephrologists sometimes have with the differential diagnosis of hyponatremic patients often results from misinterpreting the significance of measured and calculated serum osmolalities, effective serum osmolalities (tonicities), and the influence of various normal (eg, serum urea nitrogen) and abnormal (eg, ethanol) solutes. Among the more commonly held misconceptions are that high serum urea or alcohol levels will, by analogy with glucose, cause hyponatremia, and that a normal (or elevated) measured serum osmolality in a hyponatremic patient excludes the possibility of hypotonicity. This article describes typical and deliberately comparative data of the serum levels of sodium, glucose, urea nitrogen, and mannitol and/or ethanol (if present); calculated and measured osmolality; effective osmolality; and the potential risk of hypotonicity-induced cerebral edema for each of 6 prototypical hyponatremic states. This provides a helpful educational tool for untangling these interrelationships and for clarifying the differences among various hyponatremic conditions.
Table 1. Common Fables

1. That the presence of true hyponatremia means that the total body water must always be increased, that the total body sodium must always be decreased, or both
2. That high serum urea or alcohol levels will, by analogy with glucose, cause hyponatremia
3. That urea and alcohol do not contribute to measured serum osmolality
4. That a normal (or elevated) measured serum osmolality in a hyponatremic patient excludes the possibility of hypertonicity
5. That a patient with hyperglycemia-induced hyponatremia must have a normal measured serum osmolality
6. That the presence or absence of an abnormally increased osmolal gap provides definitive information regarding whether a hyponatremic patient is at increased risk for cerebral edema

*Some of these misconceptions are held concurrently despite mutual incompatibility. These fables have been debunked as follows: No. 1, see discussion of true hyponatremia and Table 3; No. 2 to 4, see discussion of cases 6 and 7 in Table 2; No. 5, see discussion of case 4 in Table 2; and No. 6, compare cases 5 and 7 in Table 2 and compare cases 1, 2, 4 and in Table 2.

| Table 2 is constructed to illustrate typical values for normal individuals and for patients with each of 7 pathological conditions, 6 of which are associated with hyponatremia. Data are provided for serum sodium, serum glucose, SUN, serum mannitol or ethanol (if either is present), Osmc, Osmm, osmolal gap, and effective osmolality, as well as the risk of cerebral edema. For illustrative consistency, the normal (typical) values of the variables are chosen as follows: serum sodium, 140 mmol/L; serum glucose, 5 mmol/L (90 mg/dL); SUN, 5 mmol/L (14 mg/dL); Osmc, 290 mmol/kg H2O; Osmm, 290 mmol/kg H2O; osmolal gap, 0 mmol/kg H2O; and effective osmolality, 285 mmol/kg H2O. All of the hyponatremic states are arbitrarily given a serum sodium level of 120 mmol/L. |

Normal

The Osmc = (2)(140) + 5 + 5 = 290 mmol/kg H2O. Because, as mentioned above, the normal osmolal gap is arbitrarily set at 0 mmol/kg H2O, the Osmm is also 290 mmol/kg H2O. The effective osmolality is 290 mmol/kg H2O minus the 5-mmol/kg H2O contribution of urea, ie, 285 mmol/kg H2O. Because the effective osmolality (or tonicity) is normal, there is no risk of cerebral edema.

True Hyponatremia

The Osmc is (2)(120) + 5 + 5 = 250 mmol/kg H2O, a value that is lower than normal; the Osmm is also 250 mmol/kg H2O, so the osmolal gap is 0 mmol/kg H2O. In this case, the effective osmolality is 250 – 5, ie, 245 mmol/kg H2O, an abnormally low value that indicates increased susceptibility to cerebral edema. Patients who are hypo-osmolal must also be hypotonic, but even patients who are either normo-osmolal or hyperosmolar may still be hypotonic (see the examples given below of true hyponatremia together with either a high SUN level or a high serum ethanol level).

Pseudohyponatremia

In a patient with profound hypertriglyceridemia, as discussed above, the serum sodium concentration (depending on the method of analysis; see “Definitions of Terms” section, above) might be reduced to 120
Therefore, the absence of an increased osmolar gap rules out pseudohyponatremia.

### Hyponatremia Caused by Severe Hyperglycemia

The hyponatremic response to hyperglycemia is variable and determined by several factors, most of which are not known or measurable during the usual clinical circumstances. Therefore, we used the correction factor of Katz, whereby the serum sodium level decreases by 1.6 mmol/L for each 5.6 mmol/L (100 mg/dL) increase in glucose level. Use of this formulation in Table 2 predicts that elevation of the serum glucose level has induced a translocation of water from the intracellular fluid to the ECF sufficient to reduce the serum sodium level to approximately 120 mmol/L. The Osmm will be (2)(120) + 5 + 5 = 250 mmol/kg H2O. An osmometer measures solutes only in the water phase of serum, and therefore the measurement is not substantially influenced by the hyperglycemia.

Because the Osmm will be 290 mmol/kg H2O, the osmolar gap will be 290 – 250 = 40 mmol/kg H2O, an abnormally high value. Thus, lipid- or protein-induced pseudohyponatremia must be associated with an elevated osmolar gap.

* Osmm, indicates calculated osmolality (calculated as 2[Na] + SUN/2.8 + GLU/18, where SUN indicates serum urea nitrogen, and GLU, glucose); Osmc, measured osmolality (we assume herein that the normal osmolar gap is zero). Osmolar gap is Osmm − Osmc.

† Effective osmolality (tonicity) is that portion of osmolality inducing transmembrane water movement; the cited values for effective osmolality were calculated by subtracting the contributions of urea and ethanol (if present) from the measured osmolality.

‡ Immediate risk of the osmotic type of cerebral edema before treatment. (The more acute the hyponatremia, the greater the risk, since osmotic adaptation is less advanced.)

§ Effect on intracellular fluid volume depends on clinical circumstances.

¶ Neglecting the correction factor for serum water content, 40 mmol of ethanol per liter corresponds to approximately 184 mg/dL.

Therefore, the absence of an increased osmolar gap rules out pseudohyponatremia.

### Hyponatremia Caused by Retention of Mannitol

If it is assumed that mannitol (molecular weight, approximately 182) exerts the same effect on a normal serum sodium level of 140 mmol/L as does glucose, a serum mannitol concentration of 75 mmol/L (1365 mg/dL) might be expected to be associated with a serum sodium level of approximately 120 mmol/L. As in the case of hyperglycemia, we are neglecting the effect of any osmotic diuresis on the serum sodium concentration. The Osmm, which does not take mannitol into account, will be (2)(120) + 5 + 5 = 250 mmol/kg H2O, an abnormally low value. (Note that this contrasts with

* These combinations of total body sodium and total body water all produce true hyponatremia; of course, any combination of total body sodium depletion together with total body water excess will also produce true hyponatremia. A downward arrow indicates decreased; an upward arrow indicates increased.

† Use of 2 arrows indicates a greater degree of abnormality.

---

mmol/L.3-5 If the SUN and serum glucose levels are normal, this must result in a subnormal Osmm; in this example, the Osmm will be (2)(120) + 5 + 5 = 250 mmol/kg H2O. An osmometer measures solutes only in the water phase of serum, and therefore the measurement is not substantially influenced by the hyperlipemia. Because the Osmm will be 290 mmol/kg H2O, the osmolar gap will be 290 − 250 = 40 mmol/kg H2O, an abnormally high value. Thus, lipid- or protein-induced pseudohyponatremia must be associated with an elevated osmolar gap.

the situation in hyperglycemia-induced hyponatremia, wherein Osm is increased.) The Osmw will be (2)(120) + 75 + 5 + 5 = 325 mmol/kg H2O; thus, the osmolar gap is 325 - 250 = 75 mmol/kg H2O, a considerably elevated level, again contrasting with the situation obtaining in hyperglycemia wherein the osmolar gap is normal. The effective osmolality is 325 – 5 = 320 mmol/kg H2O; this high value, indicative of hypotonicity, places the patient at increased risk for cerebral dehydration, rather than cerebral edema.22,23

True Hyponatremia Together With Elevated SUN Level

We have found that this situation is one of the least well understood conditions regarding the interrelationships between serum sodium, osmolality and osmolal gap, and toxicity. A patient with true hyponatremia (e.g., a patient with the syndrome of inappropriate secretion of antidiuretic hormone whose serum sodium level is 120 mmol/L) might develop incidental acute renal failure. If the SUN level were to rise to 45 mmol/L (126 mg/dL), the Osm would be (2)(120) + 5 + 45 = 290 mmol/kg H2O, a normal value. The Osmw would also be 290 mmol/kg H2O because urea’s contribution is not only measured in Osm, but also calculated in Osmw. Thus, the osmolar gap is 0 mmol/kg H2O. The important point, frequently not appreciated, is that finding a normal Osm (or even an increased Osm) does not preclude an increased risk of cerebral edema from hypotonicity. Because urea is not an effective solute (see “Definitions of Terms” section, above), the effective osmolality is 290 – 45 = 245 mmol/kg H2O, an abnormally low value. Thus, such a patient has the same increased risk of cerebral edema that he or she would have at the same serum sodium level if the SUN level were within the normal range.

True Hyponatremia Together With High Blood Alcohol Level

Instead of developing acute renal failure, suppose a patient with the syndrome of inappropriate secretion of antidiuretic hormone and with a serum sodium level of 120 mmol/L has ingested an excessive amount of ethanol. When ethanol (molecular weight, approximately 46) is present in serum, Osm increases without a change in toxicity.10,11 If the serum ethanol concentration is 40 mmol/L (184 mg/dL) in this patient, the Osm will be (2)(120) + 5 + 5 + 40 = 295 mmol/kg H2O.22 (As is the case with urea, the presence of ethanol in the ECF does not by itself affect the serum sodium concentration, because ethanol is not an effective solute.) Neglecting the correction factor for serum water content,7,10 the Osm will be (2)(120) + 5 + 5 + 40 = 295 mmol/kg H2O. Thus, the osmolar gap will be 290 – 250 = 40 mmol/kg H2O, an abnormally elevated value.

This situation contrasts with that of the azotemic hyponatremic patient discussed above, because ethanol is not a variable in the equation used herein to calculate serum osmolality. The effective osmolality is 290 – (40 + 5) = 245 mmol/kg H2O, an abnormally low value, which is indicative of an increased risk of cerebral edema. Thus, in our examples, both the patient with a high SUN level and the patient with a high alcohol level are hypotonic, but only the ethanol abuser has an increased osmolar gap.

Hypernatremia

This example is provided for contrast. If the patient has a serum sodium concentration of 160 mmol/L, the Osm is (2)(160) + 5 + 5 + 330 mmol/kg H2O; the Osmw will be the same, and therefore, the osmolar gap is 0 mmol/kg H2O. The effective osmolality will be 330 – 5 = 325 mmol/kg H2O, which is abnormally increased. Thus, a hypernatremic patient is always both hyperosmolar and hypertonic.22,23, there is no such thing as “pseudohypernatremia.”
